SECTION 1

A 4-year-old girl was seen in the pediatric emergency department because of a first generalized tonic-clonic seizure that occurred at school. The seizure was preceded by a sudden, prolonged attack of unconsciousness, lasted 5 minutes, and was followed by drowsiness.

The parents were first cousins of Algerian descent. She had an unremarkable family history. Pregnancy and delivery were uneventful. At age 4, she under-

went bilateral cochlear implantation for congenital sensorineural deafness.

Neurologic examination was notable for deafness and marked agitation, which was reported to be usual by her parents. Psychomotor development was mildly delayed.

Questions for consideration:

1. What is your evaluation of this first nonfebrile seizure?
2. Would you prescribe a treatment and, if so, which one?

Disclosure: Author disclosures are provided at the end of the article.

EEG was performed 1 day after the seizure (see Section 3 for its interpretation).

SECTION 2

When a child is evaluated for a probable first seizure, it is important to assess if it was really a seizure and if it was really a first attack. There is currently no test that proves that a seizure occurred. About half of the children with a presumed first seizure have had a prior unrecognized seizure.¹ In our patient, it was the first episode.

After it is established that a first seizure occurred, it is important to evaluate if it was a provoked seizure. Population-based studies indicate that 25%–30% of first seizures are “acute symptomatic,” indicating that they are caused by a brain insult or a metabolic or toxic disturbance of brain function.²

Among these, syncope that induces seizure is particularly challenging to diagnose. When clinical examination is normal, routine laboratory testing is unlikely to be revealing in a child with a first nonfebrile seizure.³

Rectal diazepam was prescribed in case of prolonged seizure,⁴ and oral hydroxyzine was started for psychomotor agitation.

EEG recording was done 1 day after the initial seizure (figure).

Questions for consideration:

1. What is your conclusion about diagnosis from the EEG?
2. Would you obtain additional tests?

GO TO SECTION 3

SECTION 3

A few slow spikes were noted in the posterior area of the EEG, and were considered within the normal range for her age. The electrocardiogram (ECG) channel of the EEG recording was suggestive of a cardiac conduction defect (short PR, long QT). On the figure, the black bar represents the measure of the QT space. The red bar represents the RR space permitting the evaluation of the corrected QT ($QT_c = QT/\sqrt{RR}$). In her case, the QT_c was >0.7 seconds.

A standard ECG was then performed. A long QT was confirmed (QT_c measured at 0.6 second, normal value <0.44 second), suggesting a long QT syndrome (LQTS). Hydroxyzine was immediately stopped, being contraindicated in LQTS, and beta-blocker therapy was started.

The sudden syncopal episode preceding her first seizure was therefore considered of cardiac origin, and the generalized tonic-clonic movements were considered to be secondary to transient cerebral hypoxia. Congenital deafness associated with long QT is suggestive of Jervell and Lang-Nielsen syndrome (JLNS or LQT1), and this was confirmed by the identification of a homozygous mutation of the voltage-gated potassium channel gene *KCNQ1*.

At follow-up at age 5 years, she looked healthy and calm. She had not experienced any further syncopal episodes. Neurologic examination was normal, except for bilateral deafness. Psychomotor development was within normal range. Her QT_c was 0.53 second. Awake and sleep EEG was normal.

DISCUSSION The patient presented with cardiovascular syncope, with abnormal tonic-clonic movements due to cerebral hypoxia. This etiology could have been considered at the emergency department because of sudden, prolonged unconsciousness preceding the seizure.

Misdiagnosis of epilepsy is common,⁵ especially in children. Clinically, arrhythmic episodes may be difficult to differentiate from epilepsy on clinical grounds. Seizure-related cardiac arrhythmias (i.e., bradycardia or asystole) have been reported,⁶ as well as sudden falls during focal seizures.⁷ Clinical features and EEG recording permit exclusion of the Panayiotopoulos syndrome that may mimic cardiac syncope.⁸ This is a benign, common childhood epilepsy with autonomic seizures imitating syncope, migraine, or gastroenteritis. Its autonomic manifestations may include cardiorespiratory alterations.

A delayed diagnosis of LQTS is unfortunately frequent. Long QT symptoms are often attributed to

alternative diagnoses, most commonly epilepsy.⁹ In this child, JLNS was diagnosed. It is caused by homozygous mutations of the voltage-gated potassium channel gene *KCNQ1* and is characterized by deafness and a prolongation of the QT interval at baseline ECG with a high risk of life-threatening arrhythmias or sudden cardiac death.¹⁰

Investigators recently showed that a direct link may exist between LQTS and epilepsy.¹¹ They found that patients with LQT2 (*KCNH2* mutations) had more frequent epilepsy than patients clinically evaluated and genetically tested for LQTS, suggesting that perturbations in the *KCNH2*-encoded potassium channel may confer susceptibility for recurrent seizure activity.

Given the potentially preventable mortality of LQTS, physicians investigating syncope and seizures should maintain a high index of suspicion for long QT syndrome as an etiology.

The use of EEG and ECG recordings is often necessary to make the diagnosis. When personal or family history of syncope, deafness, or abnormal ECG is present, the use of drugs that may be responsible for a prolongation of QT_c should be avoided until the investigations permit exclusion of a long QT.

DISCLOSURE

Dr. Auvin, Dr. Lejay, Dr. Delanoe, Dr. Denjoy, Dr. Lupoglazoff, and Dr. Mercier report no disclosures. Dr. Titomanlio serves as an Associate Editor of *Prospettive in Pediatria*.
