Teaching Video NeuroImages: Speech-induced oromandibular dystonia relieved by singing

We report a rare task-specific dystonia\textsuperscript{1,2} in a 26-year-old man with a 4-year progressive speech disorder characterized by oromandibular spasms. Family and medical history were unremarkable; he was never exposed to neuroleptic drugs or toxic agents. Neurologic examination revealed only speech-induced oromandibular dystonic movements, characterized by forced jaw opening, interfering with speech (video on the Neurology\textsuperscript{®} Web site at www.neurology.org). However, he was able to sing and to perform other voluntary activities (swallowing, drinking, chewing). Laboratory tests and brain magnetic resonance scans were normal. He received a placebo injection with no benefit. Trihexyphenidyl was started with moderate benefit. This rare form of dystonia is sometimes triggered by praying,\textsuperscript{1,2} resembling task-specific occupational dystonias.
