The emergence of novel coronavirus 2019 (COVID-19) and the subsequent pandemic present a unique challenge to neurologists managing patients with multiple sclerosis (MS) and related neuroinflammatory disorders, such as neuromyelitis spectrum disorder (NMOSD).

National professional bodies (e.g., Italian Society of Neurology and Association of British Neurologists) and patient organizations (e.g., National MS Society, MS International Federation, UK MS Society, and MS Australia) have responded rapidly by issuing guidelines for the COVID-19 pandemic, primarily focused on MS disease-modifying therapies (DMTs). In this commentary, we highlight the implications of COVID-19 for people with MS and related disorders, including the risk of respiratory infections, general health advice, and recommendations (from consensus-based guidelines) for immunotherapies, relapse management, and service delivery during the COVID-19 pandemic.

Risk of respiratory infections

Whether people with MS and NMOSD are at an increased risk of COVID-19 infection or at a higher risk of more severe infection is unknown. There are no data available on whether the rate of mild, self-limiting respiratory infections that do not require a medical encounter is increased in people with MS. However, there is increased infection-related health care utilization across all age groups in people with MS compared with the general population. These infections include pneumonia (particularly in people with bulbar weakness resulting in aspiration and impaired pulmonary function due to severe quadriplegia) and influenza, but not upper respiratory tract infections. Older age, male sex, worse physical disability, and lower socioeconomic status are associated with increased hospitalization rates in MS. People with MS have a higher risk of intensive care unit admission with infections and higher 1-year mortality after admission than the general population. In addition to the higher background risk of infection-related health care utilization, people with MS treated with the second-generation DMTs are exposed to a further increased risk of infections. These factors should be considered when counseling individuals about the risks of COVID-19 infection.

General health advice

People with MS and related disorders should follow World Health Organization (WHO) and national or local health authority guidance on preventive measures to reduce transmission of COVID-19 in the general population. These include social distancing, frequent hand washing with soap and water or an alcohol-based hand rub, and respiratory hygiene. Advice from the WHO is updated regularly (who.int/emergencies/diseases/novel-coronavirus-2019).
Patients should be educated about the symptoms of COVID-19 infection, including fever, cough, and shortness of breath. People with MS and related disorders should be advised not to make changes to their MS treatment without discussion with their neurologist.

Managing patients with COVID-19 infection

In people with MS and related disorders taking immunotherapy, treatment is generally continued during mild, viral infections. In those with documented mild COVID-19 infection, it may be reasonable to continue treatment. Neurologists should have a lower threshold for stopping treatment in people taking therapies with greater immunosuppressive effects and those with risk factors for a more severe disease (older age and comorbidities) or if COVID-19 symptoms are deteriorating.

Discussion should be given to stopping treatment in those who are hospitalized with severe or complicated COVID-19 infection. Treatment can be restarted after 4 weeks or when symptoms have fully resolved, keeping in mind the risk of rebound MS activity with S1P modulators and natalizumab. Neurologists should alert intensive care physicians to the importance of fever management in people with MS.

Managing patients with MS without COVID-19 infection

Acute relapses

MS relapses are frequently treated with a short course of high-dose IV methylprednisolone. Chronic use of corticosteroids is associated with an increased risk of infections, and short-term use of high-dose corticosteroids may increase the risk of herpes virus reactivation. High-dose steroids hasten the recovery from MS relapses, but do not influence the final degree of recovery. Neurologists should consider having a higher threshold for offering steroid treatment during the COVID-19 pandemic.

An acute infection will sometimes lead to a transient worsening of symptoms in MS and other disorders (pseudo-relapse). Patients should be carefully screened for symptoms of active COVID-19 infection before receiving corticosteroid treatment.

Disease-modifying therapies

A few MS therapies (interferon-β and glatiramer acetate) exert immunomodulatory effects with no increase in the risk of systemic infections. Other treatments used in contemporary MS practice do have immunosuppressive effects with alterations in lymphocyte number, trafficking, proliferation, and function, with an increased risk of infections, including viral infections and respiratory infections. It is reasonable to hypothesize that these therapies may predispose to a greater risk of COVID-19 infection and potentially more severe infection. However, at the present time, there is no evidence to support this. People with MS who are profoundly lymphopenic, for example, after treatment with alemtuzumab or less commonly during treatment with cladribine, fingolimod, or dimethyl fumarate, may be at a higher risk.

In most people with MS, the benefits of continuing treatment will outweigh the risks of stopping an MS therapy because of concerns over COVID-19 (Table). Alemtuzumab and, to a lesser extent, cladribine lead to a transient and variable period of lymphopenia after each course of treatment. We recommend delaying treatment with these therapies in patients due to receive a second or subsequent course (Table). Anti-CD20 therapies, including ocrelizumab and rituximab, are typically dosed regularly every 6 months. B-cell depletion frequently lasts much longer than the scheduled dosing interval, and extended-interval dosing should be considered, especially in patients who are B-cell depleted (as measured by CD19/CD20 lymphocyte counts) at the time of the next scheduled dose or those with low levels of immunoglobulin G. Extended-interval dosing is already widely used in patients treated with natalizumab because of observational data showing a reduced risk of progressive multifocal leukoencephalopathy. Whether this approach reduces the risk of other infections is unknown, but should be considered during the COVID-19 pandemic to reduce hospital visits.

The counseling of patients with MS who want to discuss delaying or even stopping an MS therapy will be influenced by (1) patient factors, such as age and comorbidities that increase the risk of severe COVID-19 infection; (2) disease factors, including disease activity before starting treatment and in the previous 12 months, disease course, and disability; and (3) drug factors, including the potential for rebound disease activity if treatment is stopped (e.g., S1P modulators and natalizumab).

Decisions over initiation or switching DMTs during the COVID-19 pandemic should take into account the same patient, disease, and drug factors noted above. It is safe to initiate treatment with interferon-β and glatiramer acetate and perhaps safe to start teriflunomide and dimethyl fumarate in children and young adults who are otherwise healthy (Table). The burden of treatment monitoring should be taken into account when initiating a new MS therapy, for example, monthly (or 2-weekly in Europe) liver function tests in patients starting teriflunomide may be impractical during the COVID-19 pandemic. If a high-efficacy treatment is required for patients with severe or breakthrough disease, starting or switching to natalizumab is preferable to alemtuzumab, cladribine, or ocrelizumab because the risk of systemic immunosuppression is lower and prolonged lymphocyte depletion does not occur. Treatment with natalizumab for 12–18 months is associated with a low risk of progressive multifocal leukoencephalopathy (including in patients who are JC virus antibody positive) and can be considered as a bridging therapy. There is a general consensus against autologous
hematopoietic stem cell transplantation, as it represents the highest risk of infections to patients.

Managing patients with neuromyelitis optica spectrum disorder without COVID-19 infection

Relapses in patients with NMOSD may be devastating, and patients should be encouraged to continue therapies for attack prevention including corticosteroids, azathioprine, mycophenolate mofetil, rituximab, tocilizumab, and eculizumab. If there is a clinical need to stop or delay treatment in patients with NMOSD, moderate-dose corticosteroids (e.g., prednisolone 20 mg) can be used to prevent relapses in the short to medium term.

Managing special patient groups

The risk of COVID-19 infection appears lower in children, and infections appear milder. There are no special considerations in children with MS and related disorders. Severe COVID-19 infections are more common in older adults (aged >60 years) with a higher case fatality rate. Treatment decisions in this age group should be individualized, taking into account other comorbidities that increase the risk of death (cardiorespiratory disease and diabetes) and the more modest benefits of disease-modifying treatment in older patients and/or those with progressive forms of MS. Pregnant women should follow general health advice during the COVID-19 pandemic, with no special considerations.

Implications for service delivery

Many MS centers are using telemedicine to avoid non-essential hospital visits during the COVID-19 pandemic. Telemedicine has previously been validated as a tool for assessing disability in MS with high patient acceptability. Other steps to reduce hospital visits such as home delivery of medications, delaying follow-up MRI scans in stable patients, and reducing the frequency of routine laboratory monitoring should also be considered. Oral corticosteroids may be

a Some neurologists advise dose reduction if lymphocyte counts are approaching cutoff values for discontinuing treatment, although no evidence is available to guide these decisions.
preferable to treat acute relapses, given the equivalent efficacy to IV corticosteroids, at least in patients with MS. Less frequent dosing of infusion therapies (e.g., natalizumab and ocrelizumab) may also relieve pressure on infusion centers that may be understaffed due to redeployment or illness. MRI and infusion centers have implemented additional measures to reduce the risk of COVID-19 transmission in these settings.

Conclusions
As for the general population, most patients with MS are expected to experience only mild symptoms with COVID-19 infection. Some immunotherapies may increase the risk of more severe infection and individualized risk assessment is required, taking into account the immunosuppressive effects of the treatment and other patient factors (e.g., age, physical disability, and comorbidities) and the health care setting. Collecting data on the impact of COVID-19 on people with MS and related disorders and particularly the risks of a novel pathogen in patients on immunosuppressive treatments is a priority for national and international registries. We would recommend all neurologists who become aware of a person with MS being confirmed as COVID-19 positive notify their local registry.
