Section 1

An 81-year-old right-handed woman presented to the emergency department (ED) with confusion, generalized weakness, and difficulty ambulating. In addition to several cardiovascular comorbidities (hypertension, hyperlipidemia, peripheral arterial disease, coronary artery disease, chronic kidney disease, and renal artery stenosis), her medical history was significant for stage IV carcinoma of the urinary bladder. She had been in her usual state of health until 1 week prior to her presentation when she began experiencing generalized weakness in her legs, requiring more frequent use of a walker as well as intermittent headaches and increasing forgetfulness. Two to 3 days prior to presentation, her husband noted that she was increasingly getting confused. On the day of presentation, she woke up disoriented and was too weak to get out of bed, prompting her husband to bring her to the ED. In the ED, she was afebrile, hypertensive (180/90 mm Hg), and tachycardic (heart rate 120–130/min). On mental status examination, she was intermittently oriented to time and place and unable to follow complex instructions. Her score on the Montreal Cognitive Assessment (MoCA) was 9/30. Other pertinent examination findings included left facial weakness (lower face) and left upper and lower extremity weakness (3/5). Sensory examination revealed left-sided hemineglect. The patient was unable to ambulate as she could not stand without assistance.

The patient had been diagnosed with stage IV metastatic transitional cell carcinoma of the urinary bladder 2 years before the current admission and had gone into remission following therapy with gemcitabine and cisplatin. Eight months prior, she began immunotherapy with pembrolizumab infusions every 3 weeks after a follow-up PET scan showed nodal metastases, indicative of probable disease progression. Her most recent PET scan (2 weeks before the current admission) revealed interval improvement of the nodal metastases with pembrolizumab and absence of any new lesions. Her husband reported that she had experienced pembrolizumab-related adverse effects such as rash and colitis several months prior which resolved with steroids. She had otherwise been tolerating the immunotherapy well and had received her last infusion 2 weeks prior to presentation.

Questions for consideration:

1. What is the differential diagnosis given the presentation and history?
2. What diagnostic tests would you perform?

Section 2

This presentation of altered mental status with acute/subacute-onset focal neurologic deficits certainly indicates a CNS pathology. Stroke remains at the forefront of the differential diagnoses, primarily because of the fast onset of the neurologic deficits in the background of multiple cardiovascular risk factors, including the history of myocardial infarction. However, it is important to keep the differentials wide and resist the temptation to anchor only towards stroke. Infections of the CNS (meningitis or encephalitis) remain an important differential here because of the acute to subacute onset of confusion and neurologic deficits. The patient's history of metastatic cancer makes paraneoplastic disease process and new metastasis to the meninges or brain parenchyma a reasonable differential diagnosis. Although not supported by the rapid onset of the symptoms, altered mental status and gait impairment in an elderly patient prompts the inclusion of normal-pressure hydrocephalus (NPH) into the list of differentials. Given the history of transitional cell carcinoma of the urinary bladder, cancer-associated Wernicke-Korsakoff syndrome is reasonable to consider as it may present with ataxia, altered mental status, and weakness.¹ Finally, as checkpoint inhibitors are rarely associated with autoimmune neurologic side effects including encephalitis, aseptic meningitis, and hypophysitis,² pembrolizumab-associated adverse effects are important to consider.

Among the differential diagnoses mentioned above, it is essential to evaluate for stroke first. Investigations for stroke include noncontrast CT of the head, CT angiogram, CT perfusion, and MRI of the brain (noncontrast). These investigations did not reveal any evidence of acute stroke. MRI

brain (without contrast), however, revealed ventriculomegaly out of proportion to the cortical atrophy.

Because of the ventriculomegaly, a high-volume CSF tap was essential in this case as the patient also had 2 cardinal symptoms of NPH, i.e., cognitive dysfunction and gait impairment. Opening and closing pressure, while not obtained on this patient, would be useful to measure. Moreover, CSF analysis (routine cell counts, cytologic, biochemical, and microbiological examinations) is necessary to investigate 2 differential diagnoses, i.e., CNS infection and metastasis to the meninges. MRI of the brain was repeated (with contrast) as it was essential for the remaining differential diagnoses, i.e., CNS infections, metastasis, and immunotherapy adverse effects such as aseptic meningitis or hypophysitis. In addition, the patient's lower extremity weakness and ataxic gait warranted MRI of the whole spine. Considering the history of cancer, serum paraneoplastic panel is of paramount importance. Although we did not check thiamine level to evaluate for Wernicke encephalopathy (as onset was rapid), this should be regarded as one of the important differentials in the background of advanced cancers. In addition to these targeted investigations, complete blood count, comprehensive metabolic panel, vitamin B₁₂, folate, and workup for syphilis and HIV are crucial.

A high-volume lumbar puncture (24 mL) did not result in substantial improvement in gait or cognition (MoCA remained unchanged). MRI brain (with contrast) was motion-degraded, which made visualization on any contrast enhancement difficult. However, there was leptomeningeal enhancement in the cauda equina and conus (figure, A and B). CSF analysis was significant for lymphocytic pleocytosis (18/mm³), low glucose (<1 mg/dL), and elevated protein

Figure MRI abnormalities in the lumbar segment of the spinal cord

(A) Sagittal T2 sequence of the lumbar spine demonstrating hyperintense signal changes in the L1-L2 level. (B) Sagittal T1 (postcontrast) sequence of the lumbar spine demonstrating contrast enhancement around the L1-L2 level.

Table Differential diagnoses, pertinent investigations, and their results

Categories	Differential diagnoses	Investigation	Pertinent results
Vascular	Stroke	Noncontrast CT of head, CT angiogram of head and neck, CT perfusion, MRI (without contrast)	No evidence for acute stroke Ventriculomegaly out of proportion to cortical atrophy on MRI
Neurodegenerative	Normal-pressure hydrocephalus	High-volume CSF tap with opening and closing pressures	No improvement in gait or MoCA score after high-volume CSF tap; opening/closing pressures not measured
Metabolic	Wernicke encephalopathy, B ₁₂ deficiency	Thiamine level, B ₁₂ level	Vitamin B12—within normal limits (thiamine was measured for this patient)
Infectious	Meningitis Encephalitis	CSF analysis; CSF infectious panel (HSV, VZV, West Nile, bacterial culture); T-spot; VDRL; HIV	Lymphocytic pleocytosis (18/mm ³), low glucose (<1 mg/dL), elevated protein (114 mg/dL)
Toxic/treatment related	Hypophysitis Immunotherapy-associated encephalopathy	MRI brain with contrast; TSH (hypophysitis) Urine toxicology	No signal changes in pituitary Normal TSH and urine toxicology
Cancer-related	Metastatic and paraneoplastic	MRI brain with contrast, MRI spine with contrast, CSF cytology	Leptomeningeal enhancement of cauda equina and conus medullaris Scattered malignant cells on cytology Paraneoplastic panel: negative

Abbreviations: HSV = herpes simplex virus; MoCA = Montreal Cognitive Assessment; TSH = thyroid-stimulating hormone; VDRL = Venereal Disease Research Laboratory test; VZV = varicella-zoster virus.

(114 mg/dL). Infectious workup (herpes simplex virus, Venereal Disease Research Laboratory, bacterial culture) of CSF was unremarkable. Subsequently, cytology examination of CSF revealed scattered malignant cells with enlarged nuclei and a high nucleocytoplasmic ratio in a background of reactive lymphocytes, consistent with metastatic urothelial carcinoma. Serum paraneoplastic panel was negative, and the rest of the laboratory investigations mentioned above were

within normal limits. The table summarizes the differential diagnoses for this case, pertinent investigations, and their results.

Questions for consideration:

1. What is the most likely diagnosis given these findings?
2. What is the most significant finding that supports this diagnosis?

GO TO SECTION 3

Section 3

CSF investigation was the key in this case. CSF glucose was very low (hypoglycorrhachia) in the background of elevated protein and lymphocytic pleocytosis. The major differential diagnoses for this CSF profile are tubercular meningitis (TBM) and carcinomatous meningitis. The patient did not have any signs or symptoms of TBM. She had no cough, fever, night sweats, neck stiffness, or photophobia. Importantly, T-spot was negative, and the X-ray of the chest was unremarkable, making a diagnosis of tuberculosis unlikely. Hence, the suspicion for carcinomatous meningitis became stronger. Later, positive cytology examination tilted the diagnosis in favor of carcinomatous meningitis. Enhancement of the conus medullaris and cauda equina further reinforced this diagnosis.

Carcinomatous meningitis is rare and typically occurs late in the course of the disease. It is most often a result of hematogenous spread of tumor cells to the subarachnoid space and into the CSF. Diagnosis is usually based on imaging and CSF analysis.³ The condition is most commonly associated with primary tumors of the breast or lung, as well as with melanoma.^{3,4} Carcinomatous meningitis secondary to bladder cancer is rare, and to date, only 33 case reports are available in the literature.⁵ The majority of these cases involved transitional cell carcinoma, as observed in our patient.

Questions for consideration:

1. What is the typical presentation and diagnostic workup for carcinomatous meningitis?
2. What are the treatment options and prognosis?

Discussion

Carcinomatous meningitis refers to the metastatic infiltration of the leptomeninges by malignant cells. The primary tumors are usually from lungs, breasts, and melanoma. Carcinomatous meningitis usually results in multifocal neurologic signs and symptoms.^{3,4} The spectrum and severity of the symptoms depend on the extent of dissemination of the malignant cells in the CNS. Headache, nausea, vomiting, altered mental status, and ataxia are some of the commonly reported symptoms.^{3,4} Diplopia, visual loss, hearing loss, and facial weakness are frequently reported symptoms of cranial nerve involvement.^{3–6} Spinal involvement may result in neck pain, back pain, paresthesia, weakness, and bladder and bowel dysfunction.

Multiaxial symptoms and signs in our patient (altered mental status, gait impairment, diffuse headache, nausea, weakness, and left facial droop) made the neuroanatomical localization challenging. In carcinomatous meningitis secondary to transitional cell carcinoma, the most common presenting symptoms reported are diffuse headache and mental status changes.⁷ In a review of 22 reported cases, 5 had cranial nerve involvement, and all but one of these cases had cranial nerve

VII involvement.⁷ There have been no reports of carcinomatous meningitis–associated sensory hemineglect that we are aware of, but sensory disturbance is not uncommon.⁸

The MRI and CSF examination of our patient was markedly abnormal, and this has been reported in a few cases of transitional cell carcinoma–associated carcinomatous meningitis.⁶ As this disease process can involve the entire neuroaxis, imaging of the brain and spinal cord is recommended as part of the diagnostic workup. However, findings on MRI are non-specific and may not be diagnostic on their own.^{3,5} Hence, CSF analysis is often key to the diagnosis. Repeated CSF sampling may be necessary; approximately 50% of patients have positive cytology on initial lumbar puncture whereas 75% are positive on the second, with yield increasing by 2% on each sample taken after that.³ Analysis of our patient's CSF revealed lymphocytic pleocytosis, hypoglycorrhachia, elevated protein, and positive cytology, which are the classical CSF findings of carcinomatous meningitis.

Treatment options for carcinomatous meningitis typically include chemotherapy (systemic or intrathecal) and radiotherapy. The commonly used chemotherapy agents include methotrexate, cytarabine, and thiotepe.⁴ Radiotherapy typically involves whole brain radiotherapy or craniospinal irradiation with targeted techniques such as intensity-modulated radiotherapy or proton therapy.⁹ While the median survival of untreated patients with carcinomatous meningitis is 1 month, treatment with the aforementioned modalities improves the median survival to approximately 3 months.⁷ However, prognosis may vary based on the underlying cancer. High Karnofsky Performance Status at diagnosis is significantly associated with better prognosis as well as ability to tolerate and respond to treatment.¹⁰ In patients with poor Performance Status or those who do not desire further intervention, hospice care is an important option to offer. Given her poor prognosis, our patient's family opted to undergo hospice care. She died at home 3 weeks following the initial presentation.

This case represents an unusual and serious complication of transitional cell carcinoma. While few cases have been reported in the literature, the incidence of carcinomatous meningitis in general is predicted to increase along with improved cancer survival times. Therefore, carcinomatous meningitis should be under consideration in patients presenting with multifocal neurologic deficits, particularly in those with a history of cancer. As false negatives on both imaging and CSF analysis are not uncommon, diagnosis may be difficult and often relies on clinical suspicion.

Study funding
