Neurologic complications of coronavirus infections

Avindra Nath, MD

In 1896, Sir William Osler\textsuperscript{1} said, “Humanity has but three great enemies: fever, famine, and war; of these by far the greatest, by far the most terrible, is fever.” This rings true even today.

The newly emerged severe acute respiratory syndrome coronavirus 2 (SARS-CoV2) has stricken fear and panic among the public, health care workers, patients, politicians, and financial markets. Fear strikes the minds of the unprepared. So we must ask ourselves why have we been caught by surprise? In the recent past, there have been many major epidemics. This includes Ebola, Zika, dengue, chikungunya, acute flaccid myelitis, and H1N1 influenza, to name a few. But SARS-CoV2 is different. It struck home! And so very rapidly. It emerged in the region of Wuhan in China around December last year, and by March, every state in the United States and over a hundred countries have reported cases of the infection with deaths in all the adult age groups. The predictions are dire. The entire health care system could potentially be overwhelmed and could crumble. Signs of that are already evident in New York and Washington state. Grocery stores have empty shelves, pharmacies are running out of critical medications, and there is scarcity of personal protection equipment and ventilators.

The major clinical manifestations of the SARS-CoV2 infection are due to pulmonary complications. Although most have mild symptoms, such as fever, headache, cough, dyspnea, myalgia, and anosmia, some develop acute respiratory distress syndrome about a week into the illness, which can result in death.\textsuperscript{2} Rhabdomyolysis can be a late complication of the infection.\textsuperscript{3} The mortality rate is about 3\%–4\%. Terminally, patients go into coma, which is thought to be due to hypoxia or multiorgan failure. But many unanswered questions remain. Could the headache be symbolic of viral meningitis? There is a report of detection of the virus in the CSF of 1 patient (encephalitis.info/blog/coronavirus). Does anosmia suggest involvement of the olfactory bulbs? In mouse models of coronavirus encephalitis, the virus can enter the brain transneuronally through the olfactory pathways.\textsuperscript{4} Hence, this relatively innocuous symptom could be indicative of a potentially more serious complication. Can the respiratory syndrome be due to brainstem involvement? Brain imaging and pathologic evaluation of the brain are necessary to understand the full impact of the virus. The elderly and immunocompromised patients are particularly vulnerable. Many have underlying neurologic comorbidities. Hypertension and diabetes seem to stand out as the most common comorbidities in patients with more severe manifestations of the infection. An interesting hypothesis has emerged around the use of angiotensin-converting enzyme (ACE) inhibitors to treat hypertension and diabetes to explain this phenomenon. ACE2 is the receptor for SARS-CoV2.\textsuperscript{5} The use of ACE inhibitors leads to increased expression of ACE2, making the cells more vulnerable to infection with the virus. Clinical studies are underway to test this hypothesis. ACE2 can be found on endothelial cells in the brain and can be induced in neurons, raising the possibility that strokes associated with SARS-CoV2 might be directly related to the infection, and encephalitis could be a potential complication.

There are several human coronaviruses (HCoVs). Most cause mild respiratory symptoms and resolve. However, in recent years, new coronaviruses have jumped species and infected humans with devastating consequences. Several acute neurologic syndromes have been associated with coronaviruses (table). Severe acute respiratory syndrome coronavirus 1 has been detected in the CSF of a patient with encephalitis and acute respiratory distress syndrome.\textsuperscript{6} Middle East
Seropositivity for coronaviruses has been reported in a variety of neurologic disorders, which include encephalitis, optic neuritis, multiple sclerosis, and Parkinson disease. Virus has also been isolated from the CSF and brain of patients with multiple sclerosis. Viruses implicated include HCoV-229E, HCoV-293, and HCoV-OC43. But the significance of these findings is not clear because these viruses are very prevalent and their causative role in these diseases has not been established.

In the past century, we have made tremendous progress in the prevention, diagnosis, and treatment of diseases. We can dissolve clots in the carotids, we can fix mutated genes before they can cause harm, and we can image the brain and its networks with exquisite precision, yet we have been brought down to our knees by the tiniest of organisms, about 60 nm in size. We need to retool and rethink how we train physicians in the practice of neurology and physician scientists in the academic neurology and how we prioritize drug development for neurologic diseases, and we need to enable academia and pharma to develop treatments not based on profits but rather on costs to humanity. Although we all recognize the hundreds of viruses that can cause encephalitis and result in devastation to large populations, we have no treatment for any of these organisms except for herpes encephalitis. It is time for us to recognize that we are facing a crisis in neurology. The time to take action is now.
