Key Words: ptosis, POLG myopathy, cricopharyngeus prominence, mitochondrial myopathy, oculopharyngeal muscular dystrophy

Study Funding:

No targeted funding reported.

Disclosures:

The authors report no disclosures relevant to the manuscript.
Section 1:

A 40-year-old gentleman presented with slowly progressive weakness and eyelid droopiness. His symptoms began in his early 30s as increased fatigue with exertion. In his mid 30s, he developed droopy eyelids without double vision. About 3 years before presentation, he started having progressive difficulty swallowing, initially with solid food but later with both solid and liquid consistencies. He also reported the food getting stuck in his throat. He had been treated for aspiration pneumonia once. A year later, he noticed slowly progressive limb weakness affecting his hands and proximal lower limbs, described as difficulty holding a tablet at church, frequently dropping objects from his hands, and difficulty with standing up from a seated position. More recently, he started experiencing dyspnea on exertion and mild orthopnea. He occasionally experienced blurry vision without diplopia, mild head drop and hoarseness of voice mainly towards the end of the day or when he is tired. He was diagnosed with seronegative myasthenia gravis at a local facility, with negative acetylcholine receptor, muscle-specific kinase (MUSK), and Low-density lipoprotein receptor-related protein 4 (LRP4) antibodies. Past medical and social history were otherwise unremarkable. The patient’s father was French-Canadian. The patient also had Native-American, and African-American ancestry. There was no family history of myopathy or any neuromuscular disorder. Neurological examination was significant for moderate bilateral ptosis, bilateral ophthalmoparesis with limited upward gaze and to a lesser extent horizontal gaze (both eye abduction and adduction), mild weakness of both upper and lower facial muscles, moderate weakness of the proximal lower extremities most prominent at the hip abductors [Medical Research Council (MRC) grade 3 to 4-/5], and mild (MRC grade 4) weakness of finger extensors and intrinsic hand muscles. He had no
demonstrable fatigable weakness on examination in any of the affected muscles. He had a mildly waddling gait and absent ankle jerks bilaterally. Sensory and coordination evaluations were unremarkable.

Questions for consideration:

1. What is the localization for the patient’s symptoms and exam findings?
2. What investigations would you perform?

Section 2:

The pattern of weakness manifesting with bilateral symmetric distal upper and proximal lower limb weakness, without any upper motor neuron signs, and the presence of marked bilateral ptosis would be unusual for a central nervous system etiology and indicates a peripheral nervous system disorder. While any defect along the motor pathways can result in dysphagia and dyspnea, especially at advanced stages, the predominant ptosis and extra-ocular muscle involvement are more suggestive of a neuromuscular transmission defect or a myopathy, rather than a motor neuropathy or neuronopathy. With no evidence of demonstrable fatigability on examination, the patient-reported fluctuation of the weakness with diurnal variation is not necessarily specific for a neuromuscular transmission defect, and hence a myopathy should still be considered. Furthermore, patients with myopathy can have a component of muscle fatigue. It is noteworthy that the presence of ophthalmoparesis without diplopia would be unusual for myasthenia gravis, and is more likely to be due to a slowly developing process such as a hereditary myopathy. The slow progression rate and the clinical phenotype with ptosis and
ophthalmoparesis would make an acquired myopathy, such as an inflammatory myopathy, less likely.

To further refine the localization, electrodiagnostic testing was performed. Upper and lower limbs, sensory and motor nerve conduction studies were normal except for a borderline low sural sensory nerve action potential amplitude of 6 µV (normal >6 µV). Two Hz repetitive nerve stimulation of the facial, spinal accessory and ulnar nerves, at rest and post exercise, were normal. Needle electromyography (EMG) showed early recruitment of short duration, low-amplitude motor unit potentials often with increased phases and turns, in proximal and distal, upper and lower limb muscles as well as in cranial muscles. Fibrillation potentials were present in cranial muscles, proximal upper limb muscles and in tibialis anterior. These electrodiagnostic findings were consistent with a myopathic process.

Laboratory work up was remarkable for an elevated Creatine Kinase of 550 (normal 52-336 U/L). Blood tests including liver function, renal function, TSH and lactate level were normal. Myositis autoantibody panel and acetylcholine receptor binding antibodies were normal as well. A video swallow study showed moderate oropharyngeal dysphagia with marked prominence of the cricopharyngeus muscle (figure 1). Pulmonary function tests showed a normal vital capacity, but a decreased maximal expiratory pressure. Overnight oximetry showed evidence of a mild sleep-related disordered breathing.

Questions for consideration

1. Based on these results, what types of myopathy would you consider on the top of your differential?
Section 3:

The electrodiagnostic testing confirmed the presence of a myopathy. The slowly progressive clinical course is suggestive of a hereditary myopathy. With the absence of other affected family members, the mode of inheritance remains unclear. While the pattern of weakness predominantly affecting hip girdle muscle can be seen with a wide spectrum of hereditary myopathies, the marked ptosis and ophthalmoparesis help narrowing down the differential diagnosis to include oculopharyngeal muscular dystrophy (OPMD), mitochondrial myopathy, or a congenital myopathy\(^1\). Among the congenital myopathies, \textit{RYR1}-related myopathy can have prominent ptosis with or without ophthalmoplegia\(^2, 3\). In its classical form, \textit{RYR1}-related myopathy is usually associated with central core disease on muscle histopathology and is inherited in an autosomal dominant pattern. However, autosomal recessive forms, that can be associated with multiminicore disease or centronuclear myohistopathology, can have more prominent ptosis. Interestingly, mutations in other genes associated with a centronuclear myopathy, such as \textit{MTM} and \textit{DNM2}, and congenital fiber type disproportion or a cap myopathy such as \textit{TPM2} or \textit{TPM3}, can also cause a myopathy with neuromuscular transmission defect, associated with prominent ptosis with or without ophthalmoparesis\(^4, 6\). On the other hand, marked ptosis is relatively common in congenital myasthenic syndromes, and the presence of a myopathy with fibrillation potentials does not rule out such conditions, as many of the genes such \textit{ALG2}, \textit{ALG14}, \textit{DPAGT1}, \textit{GMPPB}, \textit{PLEC}, and \textit{GFPT1} can cause both a myasthenic syndrome and a myopathy\(^7\). Furthermore, congenital myasthenic syndromes can rarely present with normal repetitive nerve stimulation. Based on the clinical phenotype with the prominent dysphagia and the markedly prominent cricopharyngeus muscle, in a patient of French Canadian-Native American
background, we had strong suspicion for OPMD. Subsequently, the patient was tested for this condition but had no GCN repeat expansions in the PABPN1 gene.

Questions for consideration

1. Is the possibility of OPMD completely ruled out?
2. What will be your next step?

Section 4:

OPMD is an autosomal dominant condition secondary to expansion of a GCN trinucleotide repeat in exon 1 of the polyadenine binding protein nuclear 1 gene (PABPN1). However, point mutations have also been reported and had to be ruled out. Therefore, sequencing of the PABPN1 gene was performed in our patient but showed no mutations. At this point, we decided to pursue a left gluteus medius muscle biopsy to guide further genetic testing. It showed frequent ragged-red, ragged-blue and cytochrome C oxidase negative fibers with rare atrophic and regenerating fibers indicating a mitochondrial myopathy (figure 2). Subsequently, we performed mitochondrial genome analysis on the muscle specimen which was normal with no mutations or deletions. Thereafter, we obtained a mitochondrial nuclear gene panel which showed 2 mutations in POLG: 1) p.Arg1096His (c.3287G>A), an established pathogenic mutation; and 2) p.Arg953Cys (c.2857C>T) a likely pathogenic mutation. Patient’s asymptomatic mother and brother both were tested and carried the p.Arg1096His mutation indicating that the two mutations were hetero-allelic.
Discussion:

Mitochondrial myopathies can be caused by mutations in either mitochondrial DNA (mtDNA) or nuclear genes. Mutations in mtDNA may affect only a proportion of the multiple copies of mtDNA within each cell, and result in the presence of both normal and mutant mtDNA, a phenomenon known as heteroplasmy. The degree of heteroplasmy can vary between cells in the same tissue or organ, between different organs within the same individual, and also between individuals in the same family. Therefore, manifestations of a mitochondrial disorder reflect tissue-specific mutation load, and hence it is essential that analysis of mtDNA is performed from the muscle tissue when myopathy is suspected. Progressive external ophthalmoplegia (PEO) with or without associated limb myopathy can be seen with both primary mitochondrial and nuclear DNA defects. Primary mtDNA defects can be due to point mutations or a single large mtDNA deletion. Among single large deletion disorders, patients can have a spectrum of clinical manifestations ranging from a pure myopathic presentation (i.e. pure PEO) to multisystem involvement as seen in Kearns-Sayre syndrome, with associated pigmentary retinopathy, hearing loss, short stature or cardiac conduction abnormalities. A growing list of nuclear genes encoding proteins involved in maintenance, transcription and or translation of mtDNA have been reported in mitochondrial disorders, including POLG. POLG encodes the catalytic subunit of Polymerase γ (POLG), the sole DNA polymerase enzyme responsible for mitochondrial DNA (mtDNA) replication and repair. Mutations in POLG can be associated with a wide spectrum of clinical manifestations ranging from encephalopathy and epilepsy, to sensory ataxia and myopathy, presenting from neonatal period to late adult life. From a myopathy standpoint, patients may present with PEO with or without an associated limb myopathy, in an autosomal dominant or
recessive pattern of inheritance. Patients may also present with limb weakness without extraocular muscle involvement\textsuperscript{12}. The two mutations detected in our patient have been described in association with chronic progressive external ophthalmoplegia\textsuperscript{13, 14}.

The cricopharyngeus muscle is an essential part of the upper esophageal sphincter and its relaxation allows forward passage of food bolus during the oropharyngeal phase of the swallowing. Failure to relax or early closure can cause dysphagia symptoms and imaging studies may show a posterior indentation on the pharyngeal wall, described as ‘prominent cricopharyngeus’ or a cricopharyngeal bar. It is noteworthy that this can also be an asymptomatic incidental finding associated with aging. Nevertheless, this is not a specific finding for OPMD as it can also be seen in myotonic dystrophy and inflammatory myopathies especially inclusion body myositis, sometimes requiring dilation or myotomy. Prominent cricopharyngeus or cricopharyngeal achalasia has been rarely reported in mitochondrial myopathies including mitochondrial DNA deletion syndrome\textsuperscript{15, 16}.

Herein, we reported a case of progressive ptosis, dysphagia and limb weakness, with marked cricopharyngeus prominence, due to two heterozygous mutations in \textit{POLG}. Even though OPMD is more common in people with French-Canadian origin, alternative etiologies, such as a mitochondrial myopathy may present with similar phenotype, and should also be considered.
