**Section 1**

A 59-year-old man presented with slowly progressive weakness. During childhood, he had difficulty climbing stairs. At 30, he noted difficulty getting out of a chair or standing up from the floor without using his arms. At 48, he started having 3-4 falls per year. He denied orthopnea and dyspnea. He had well-controlled hypothyroidism and hyperlipidemia. Medications included levothyroxine and niacin, and he denied the use of statins, fibrates, steroids and alcohol intake. His parents (unrelated), sister and 2 sons (ages 16 and 18) had no weakness. His maternal grandfather had leg weakness with difficulty climbing stairs around age 30 and was wheelchair bound by age 60.

Examination revealed atrophy in the bilateral quadriceps. Tone was normal and no fasciculations were present at rest or with muscle contraction. Cranial nerves were intact without facial weakness. He had mild bilateral biceps weakness (Medical Research Council [MRC] grade 4) and moderate symmetric proximal lower extremity weakness (MRC grade 3-4) in the iliopsoas and quadriceps. His infraspinatus, deltoids, triceps and distal muscles had normal strength. Clinical myotonia was not observed. Tendon reflexes were reduced throughout. He was unable to rise from a seated position without using his arms. His gait was slow with a decreased stride length and narrow base. Sensory exam was normal.

Questions for consideration:

1. Where would you localize this process?
2. Is this an acquired or inherited disease?
3. What testing would be helpful to narrow the differential?

**Section 2**

Given the lack of sensory involvement, possible localizations include anterior horn cells, motor nerve roots, neuromuscular junction, and muscles. His presentation of symmetrical biceps and lower
extremity proximal weakness is most consistent with a myopathy. Neuromuscular junction conditions such as myasthenia gravis or congenital myasthenia syndrome, and less frequently, anterior horn cell diseases such as spinal muscular atrophy type 3 and 4, can also present in this way. The absence of fasciculations or prominent atrophy makes an anterior horn cell condition less likely, and the lack of fatigability argues against a neuromuscular junction disease. The childhood onset, along with the slowly progressive symptoms, makes an inherited myopathy most likely. The patient’s maternal grandfather is also affected, and his parents, sister and sons spared, which increases the possibility of X-linked recessive inheritance. In X-linked recessive disorders, male to male transmission is never present, and the daughters of affected individuals are obligate carriers.

Creatine kinase (CK) levels may be helpful in localization. An elevated CK level usually localizes the problem to the muscle, although anterior horn cell diseases can also show mild CK elevations. However, a normal CK level can be seen in many inherited myopathies. Electrodiagnostic testing (EDX) would help differentiate between a myopathy, neuropathy and neuromuscular junction disorder. An EKG and an echocardiogram can evaluate for cardiac involvement. His serum CK was mildly elevated (281-554 IU/L; normal <240 IU/L). EMG showed abnormal spontaneous activity, diffuse myotonic discharges, and widespread myopathic motor units. Nerve conduction studies were normal. EKG showed a first degree AV block and the echocardiogram was normal.

Questions for consideration:

1. Based on these findings, what is the differential diagnosis?
2. What additional testing would you perform to clarify the diagnosis?
Section 3

The clinical history, CK elevation, and myopathic features on EMG are consistent with an inherited muscular disease. Differential diagnosis for inherited muscle disorders with progressive limb-girdle weakness and diffuse myotonic discharges include myotonic dystrophy type 2 (DM2), and vacuolar myopathies, particularly Pompe disease and X-linked myopathy with excessive autophagy (XMEA) (Table 1).\(^1-3\) Myofibrillar myopathies can exhibit vacuolar changes as well and clinically present in a similar fashion.\(^4\) Rarely, Limb girdle muscular dystrophy (LGMD) 2A (calpainopathy), LGMD 2B (dysferlinopathy) and LGMD 2L (anoctamin) can present with electrical myotonia.\(^1\)

The presence of diffuse myotonia should prompt consideration of non-dystrophic myotonias, such as myotonia congenita, paramyotonia congenita and hyperkalemic periodic paralysis. However, these patients typically present with episodic symptoms and clinical myotonia which differs from this case.

Given the possible X-linked inheritance pattern and proximal weakness, Becker muscular dystrophy should be considered. However, these patients typically present with prominent cardiomyopathy and without electrical myotonia.\(^1\)

At this point, testing of acid alpha-glucosidase (GAA) activity and CCTG repeat expansion in the ZNF9 gene would be helpful in diagnosing Pompe disease and DM2, respectively. If these tests are not conclusive, a muscle biopsy could lead to diagnostic clues.

GAA activity and genetic testing for DM2 were normal. Muscle biopsy of the right vastus lateralis is shown in Figure 1. The myopathic features (rounded fibers, scattered split fibers and internalized nuclei) and prominent adipose infiltration indicated a chronic muscle condition (dystrophy). Electron microscopy showed an abundance of variably sized autophagic vacuoles. There was no accumulation of glycogen seen on periodic acid Schiff (PAS). The described combination of features represented a chronic myopathy with excessive autophagy.
Questions for consideration:

1. Based on the muscle biopsy findings, what is the differential diagnosis?
2. What additional testing would help determine the definite diagnosis?

Section 4

The three best-defined autophagic vacuolar myopathies are Pompe Disease, Danon Disease, and XMEA.

Late-onset Pompe disease is unlikely since there was no glycogen excess on PAS or electron microscopy and the GAA activity was normal. Danon disease is an X-linked dominant disease secondary to LAMP-2 mutations that typically presents with mild progressive proximal weakness, hypertrophic cardiomyopathy, cognitive impairment, and frequently, pigmentary retinopathy. The lack of heart, ocular and cognitive involvement makes this less likely.

XMEA is an X-linked recessive disorder that usually presents in the first 2 decades of life. The progression is very slow and many patients are still ambulatory after age 50. There is no cardiac or cognitive involvement, which helps in differentiating it from Danon disease, and the EMG typically shows diffuse myotonia despite the absence of clinical myotonia. Based on the clinical phenotype, inheritance pattern, EMG findings and histologic features, XMEA was suspected. The gene for this condition was not yet identified at the time of diagnosis, but later became known. VMA21 sequencing revealed a pathogenic hemizygous mutation consisting of a single-nucleotide substitution (Exon 3, c.*6A>G). This variant has been observed in different families affected with XMEA, which confirmed the diagnosis.

Discussion

This case highlights the importance of integrating the clinical phenotype, electrodiagnostic findings and histological features when determining the etiology of an inherited myopathy. The presence of
diffuse electrical myotonia indicates hyperexcitability of the muscle membranes and may reflect structural sarcoplasmic changes. Besides myotonic dystrophy, vacuolar myopathies should also be considered in patients with progressive weakness and electrical myotonia, especially if there is no evidence of clinical myotonia.

Genetic testing options for neuromuscular disorders have recently grown significantly. The implementation of phenotypic-specific gene panels, such as muscular dystrophy panels that include LGMD and XMEA, has increased the diagnostic yield in individuals with inherited myopathic diseases. However, results can be inconclusive and variants of uncertain significance (VUS) are frequently identified. When a VUS is recognized, it is important to determine the clinical and pathological findings associated to that gene mutation, and identify the frequency of the VUS in genome databases. If the patient presents with clinical characteristics similar to the ones associated with mutations in that particular gene and the VUS is not present in population databases (or the frequency is lower than 0.01%), then the VUS is most likely pathogenic; otherwise, the VUS is probably an incidental finding. Genetic counseling provided by genetic health-care professionals should be considered when ordering genetic testing, especially when a VUS is found. In cases where genetic testing does not provide an answer, a precise phenotypic characterization of the patient can lead to the diagnosis once the causative gene is discovered. In our case, we determined that the patient’s phenotype was consistent with an inherited X-linked vacuolar myopathy before the VMA21 gene was linked to the disease. This helped target the specific mutation once the gene was discovered.

Our patient was diagnosed with XMEA due to a VMA21 mutation. The primary function of VMA21 is to regulate the assembly of the vacuolar ATPase (V-ATPase) which maintains the lysosomal acidity. Therefore, VMA21 mutations cause a rise in the lysosomal pH which alters the autophagic process and potently induces autophagy. This results in the accumulation of autophagolysosomes with incompletely
The histologic hallmark is the presence of numerous autophagic vacuoles with accumulated sarcolemmal proteins and deposition of complement C5b-9. Classic XMEA affects limb-girdle muscles, predominantly in the lower extremities, and presents during childhood, but neonatal and late-onset cases have also been reported. The progression is very slow, extramuscular organs are not clinically affected and CK typically ranges from 400 U/L to greater than 4000 U/L. Our patient demonstrated minimal progression of the disease over the next 8 years after diagnosis and he continues to be fully independent. Accurate diagnosis allowed for early diagnosis of XMEA in his second-degree cousin. This emphasizes the importance of genetic counseling in X-linked disorders, especially in female family members of childbearing age who may be asymptomatic carriers.

No specific therapies are available for XMEA. Management is symptomatic including maximization of mobility and reduction of joint contractures.
