Section 1

A 67-year-old right-handed woman presented with progressive dizziness and nausea.

She had a history of high-grade serous ovarian carcinoma with extension into the colon diagnosed one and a half years prior and had previously undergone chemotherapy and sigmoid resection with total abdominal hysterectomy and bilateral salpingo-

ophorectomy. She also had a history of type 2 diabetes mellitus complicated by peripheral neuropathy.

She reported several months of progressive dizziness and imbalance, which acutely worsened a few days prior to presentation. Her dizziness was described as a room-spinning sensation and resolved when she closed her eyes. She also reported new-onset horizontal diplopia and oscillopsia, which abated with closure of the right eye. In addition, she complained of right ear fullness without tinnitus.

On neurologic examination, she had multiple oculomotor abnormalities including limited abduction of the right eye, right-beating nystagmus with right gaze, and vertical nystagmus with primary gaze. Additionally, she had right ear conductive hearing loss, leftward tongue deviation, and dysarthria characterized by slurred speech with pronounced variation in prosody. The motor exam was normal. The sensory exam revealed loss of pinprick, temperature-sense, proprioception, and vibration distally in all extremities. She was areflexic throughout. Severe axial and appendicular ataxia were noted, and she was unable to stand or ambulate.

Questions for consideration:

1. What is the localization of this presentation?
2. What is the differential diagnosis?
3. What initial investigations will help to narrow the differential?

Section 2

The patient presented with subacute progressive non-positional vertigo, diplopia, gait impairment, and dysarthria. Her exam revealed multiple cranial neuropathies (including significant ophthalmoplegia and multi-directional nystagmus), ataxia and diffuse areflexia. Altogether, the findings of multiple cranial neuropathies and subacute ataxia are concerning for diffuse brainstem and cerebellar processes. Her examination additionally demonstrated peripheral neuropathy. A new peripheral nervous system diagnosis was considered, but this finding was ultimately felt to be consistent with her known diabetes-related or post-chemotherapeutic peripheral neuropathy.

The differential diagnosis for this constellation of findings is broad, including but not limited to autoimmune/inflammatory processes, paraneoplastic disease, demyelinating disease, multifocal vascular disease, metabolic dysregulation/nutritional deficiencies, prion disease, infection, toxin exposure, and genetic diseases. Table 1 includes examples of etiologies initially considered, with the top considerations being a malignant or paraneoplastic process given her cancer history.

Initial investigations included brain MRI with and without gadolinium, MRA head/neck, and lumbar puncture. The brain MRI revealed mild diffuse volume loss, mild subcortical and periventricular white matter changes suggestive of chronic small vessel ischemic disease, and mild enhancement along the pial surface of the bilateral cerebellar

hemispheres (Figure 1). The MRA was unremarkable. Our patient's CSF profile was notable for lymphocytic pleocytosis with a cell count of 91 cells/ μ L (88% lymphocytes, reference range 0-5), red blood cell count of 693 cells/ μ L (reference range 0-5), elevated protein of 179 mg/dL (reference range 15-45), and normal glucose of 70 mg/dL (reference range 40-80) with serum glucose 132 mg/dL. Flow cytometry and cytology on CSF samples were negative. The patient also completed a CT chest/abdomen/pelvis with contrast which revealed enlarged right retrocrural and hilar lymph nodes along with ground glass opacities in the right upper lobe of her lung. Vitamin studies, including B12, E, and thiamine, as well as thyroid studies, were within normal limits.

Questions for consideration:

1. Do these results change your differential?
2. What additional investigations should you pursue?

Section 3

The findings of pial enhancement along the bilateral cerebellar hemispheres, as well as lymphocytic pleocytosis and elevated protein on CSF studies raised most concern for an infectious cause, a paraneoplastic process, or metastatic disease. Indolent infections such as neurosyphilis, progressive multifocal encephalopathy (related to HIV infection or immunosuppression), CNS Whipple disease and infectious encephalitides with predilection for the brainstem, such as enterovirus and parechovirus, are rare but were all considered. Given concern for a primary malignant process, specifically

leptomeningeal carcinomatosis, repeat lumbar puncture was performed with additional flow cytometry and cytology showing no cancerous cells, although the negative predictive value of these studies is known to be low.¹ CSF infectious studies including VDRL, HIV, West Nile Virus, enterovirus, and parechovirus were all negative. Additional testing revealed CSF-restricted oligoclonal bands, indicative of an intrathecal immunological phenomenon. Serum autoimmune paraneoplastic panel returned positive for Purkinje Cell cytoplasmic antibody type 1 (PCA-1-IgG or anti-Yo), with a titer of 1:61,440 consistent with a diagnosis of paraneoplastic cerebellar degeneration (PCD) with anti-Yo antibodies.

Questions for consideration:

1. What treatment would you start?
2. What prognosis would you expect?

Section 4

Given the initial concern for an unspecified autoimmune/inflammatory process with ophthalmoplegia, ataxia, and dysarthria, the patient was initially treated with intravenous immunoglobulin (IVIg) 2 grams/kg given over 4 days. The patient had mild subjective improvement in her diplopia; on exam there was some improvement but no resolution of the nystagmus and dysarthria. The rest of the neurologic exam including truncal and limb ataxia remained the same. Endobronchial ultrasound bronchoscopy with biopsy of pulmonary lymphadenopathy was performed to rule out another primary malignancy

and showed only normal lymphoid tissue. Repeat cancer antigen 125 level (CA-125) was mildly elevated, but restaging of her ovarian carcinoma otherwise demonstrated no recurrence. To treat anti-Yo paraneoplastic syndrome, plans were made to continue with IVIg 1gram/kg every 3 weeks and initiation of cyclophosphamide was considered. Unfortunately, the patient fell out of bed and developed a subdural hematoma. Given the change in her clinical status, the patient and family decided against pursuing further treatment.

Discussion

Paraneoplastic cerebellar degeneration (PCD) is a common presentation of antibody-associated paraneoplastic neurologic syndromes, accounting for 36% of definite paraneoplastic cases in one study.² The criteria for a definite paraneoplastic neurological syndrome is defined as a classical syndrome and cancer that develops within 5 years of neurologic symptom onset.³ If a paraneoplastic antibody is detected, search for a primary neoplasm must be conducted.³ The most common variant of PCD is associated with anti-Yo antibodies (or Purkinje cell cytoplasmic antibody type 1); it accounts for nearly 50% of cases.⁴ The majority of cases have been reported in women with pelvic or breast tumors (like our patient with high grade serous ovarian carcinoma).⁴ A few cases associated with lung malignancy have been reported.⁵ The typical presentation involves subacute development of cerebellar deficits with plateau of symptoms within 6 months.⁴ Other auto-antibodies that produce a similar PCD picture include anti-Hu (lung cancer), anti-Tr (Hodgkin's lymphoma), anti-Ri (most commonly

associated with gynecologic and breast cancers), and anti-metabotropic glutamate receptor type 1 (Hodgkin's lymphoma).²

In one large study of 55 patients with anti-Yo autoantibody-related PCD, neurologic symptoms preceded the diagnosis of malignancy by up to 15 months.⁶ Most patients with known cancer had limited oncologic disease at the time of onset of neurologic symptoms.⁶ Three of the 55 patients studied presented with neurologic symptoms coincident with recurrence of malignancy that had previously been thought to be in remission.⁶ In addition to a pan-cerebellar syndrome with ataxia of the limbs and trunk, symptoms suggestive of brainstem involvement are often noted (similar to our patient with multiple cranial neuropathies), and commonly cognitive and psychiatric deficits follow.⁶ Early in the disease course, MRI of the brain is typically normal, with late cerebellar atrophy occurring in some patients.⁶ Rarely, cases of cerebellar edema and associated diffuse leptomeningeal enhancement have been reported, but we are not aware of any prior cases of isolated leptomeningeal enhancement, as seen in our patient.^{7,8} CSF abnormalities primarily include elevated protein, lymphocytic pleocytosis (more common shortly after symptom onset), and the presence of CSF-restricted oligoclonal bands.⁶

With regard to pathogenesis, neurologic symptoms are the result of tumor-induced autoimmunity against cerebellar antigens.⁹ An underlying immunologic reaction occurs with cerebellar degeneration-related protein 2 (CDR2) that is ectopically produced by

tumor cells leading to loss of immune tolerance to this protein and synthesis of the autoantibody.¹⁰ Research is ongoing regarding the relative importance of autoantibodies and cytotoxic T lymphocytes in the neuronal loss seen with this condition.⁹

There are no evidence-based treatment options for PCD.¹¹ However, steroids, IVIg, plasmapheresis, and a variety of immunotherapies have been used with varying degrees of success.¹¹ The Yo antigen is an intracellular onconeural antigen rather than a cell surface antigen, thus unlikely to be reached without a cytotoxic immunotherapy, such as cyclophosphamide.¹² No specific immunotherapy has been consistently shown to improve outcomes.¹⁰ Survival from time of diagnosis has been reported to be a median of 13 months.² There has been evidence of better prognosis with breast cancer-related anti-Yo PCD than that associated with ovarian cancer.⁸ The majority of patients in prior studies died of progressive neurologic disability, with age $\geq$ 60 and higher Rankin Scale scores predicting worse outcomes.² PCD remains a difficult condition to promptly recognize and treat.
