Abstract

An immunocompetent 47-year-old man presented with a five-month history of progressive lower limb weakness, back pain, sphincter dysfunction, and intermittent fever, suggesting myelopathy in a chronic deteriorating course. A comprehensive analysis comprising of blood tests, neuroimaging, CSF profiling, molecular analysis, and histopathology was performed. Notably, enhanced spinal cord MRI revealed longitudinally extensive intradural-extramedullary lesions involving the cervical, thoracic, and lumbosacral spinal cord, with homogeneous enhancement and spinal cord compression. Serum TPHA and RPR tests were positive. CSF profiling showed pleocytosis, significant protein elevations, hypoglycorrhachia,

and positive TPHA test. 18F-FDG-PET/CT indicated slightly increased intraspinal FDG uptake. Spinal cord biopsy further showed small round blue cells in poorly differentiated tissues. Immunostaining was positive for NKX2.2, CD56, CD99, Synaptophysin, and Ki67 (50%). Molecular analysis detected a novel MALAT-CYSLTR1 fusion protein and variants in oncogenic genes including *PTCH1*, *TERT*, *CREBBP*, *SPEN*, and *STK11*. The diagnosis of intraspinal extraosseous Ewing's sarcoma (ES) was confirmed. Briefly, our case details the diagnosis of a patient with intradural-extramedullary ES and highlights the value of spinal cord biopsy in progressive myelopathy of unknown causes.

Section 1

An immunocompetent 47-year-old man presented with a five-month history of worsening lower limb weakness. Initially, he noticed numbness and weakness in the left leg and had slight gait difficulty. Over the next five months, the symptoms progressed to the right leg, to the point of being unable to walk. Two weeks ago, he also developed neck pain, urinary retention, and constipation. The pain was severe and persistent, radiating into the shoulders and lumbosacral region. One week prior, he experienced intermittent fever. Upon physical examination, he was alert and oriented, with a temperature of 38.2 °C and nuchal rigidity. Cranial nerves were intact. The strength and tone of upper limbs were normal. Lower limb strength was rated 0/5 bilaterally, with decreased muscle tone. Deep tendon reflexes of the upper limbs were rated 2+. Lower limbs were areflexic. Abdominal reflexes were bilaterally absent. Babinski sign was present bilaterally. There was no ankle clonus. Sensation to pinprick and vibration were diminished below the sternal angle, suggesting a T2 sensory level.

Where would you localize the lesion?

What is your initial investigation approach?

Section 2

Progressive lower limb weakness, sphincter dysfunction, and T2 sensory level are classic features of myelopathy. Longitudinally, the neck pain, T2 sensory level, absence of abdominal reflexes, and flaccid paralysis in lower limbs suggested involvement of the cervical, thoracic, and lumbosacral segments. Transversely, impaired structures may include anterior horns (areflexic lower limbs), posterior funiculus (diminished vibratory sensation), corticospinal tracts (presence of Babinski sign), posterior horn and spinothalamic tracts

(diminished sensation to pinprick). Temporally, as this patient has a chronic deteriorating course, disorders that worsen rapidly such as spinal cord infarction or disc herniation were less likely. Taken together, longitudinally extensive transverse myelopathy with a chronic deteriorating course should be considered at this stage. Differential diagnoses include infection, neoplasms, sarcoidosis, spinal arteriovenous fistula, demyelination, and metabolic disorders. The initial investigation approach should include routine screenings for these etiologies, as well as CSF analysis and enhanced cerebrospinal MRI.

Blood tests were notable for increased inflammatory markers and positive syphilis antibodies (eTable 1). Pulmonary CT and ECG were unremarkable. Enhanced brain and spinal cord MRI revealed longitudinally extensive lesions involving the cervical, thoracic, and lumbosacral spinal cord. The spinal cord was compressed, slightly hypointense on T1-weighted images and hyperintense on T2-weighted images. The lesions were posterior to the spinal cord, iso- to hyperintense on T1-weighted images and hypointense on T2-weighted images, with well-defined borders and homogeneous enhancement (Figure 1). Upon lumbar puncture, CSF pressure was 390 mmH₂O. Less than 2ml of yellow-colored CSF was collected due to hypercoagulability. CSF profiling showed pleocytosis (total cell count $120 \times 10^6/L$, a white blood cell count $12 \times 10^6/L$, polynuclear cells 60%), significant protein elevations (5.56 g/L), decreased glucose levels (1.6 mmol/L), a positive TPHA test, and a negative RPR test. Blood, urine, and stool cultures detected no bacteria or fungi, nor did the result of CSF next-generation sequencing (NGS).

What is your differential diagnosis at this stage?

Section 3

The ascending sensory disturbance, late-onset sphincter dysfunctions, significantly elevated CSF protein levels, and unique spinal MRI findings suggested an intradural-extramedullary lesion extending through multiple segments. Additionally, the CSF hyperproteinosis, xanthochromia, and hypercoagulability indicated Froin's syndrome, which together with the CSF pleocytosis and hypoglycorrhachia are highly suggestive of infectious or neoplastic disorders.

Infections that can form long segmental abscesses or granulomas in the subdural space need to be considered. Tuberculosis, fungus, and brucella were excluded as the exposure history

and relevant pathogen tests were negative. The patient was positive for TPHA in both serum and CSF, suggesting neurosyphilis. Anti-syphilitic treatment with penicillin was indicated. However, the spinal MRI findings of our patient were very uncommon for neurosyphilis. Pathologically, intradural-extramedullary syphilitic myelopathy is most likely caused by syphilitic gumma¹. The MRI findings typically present as short-segment T2 hyperintensities, with nodular or ring-like enhancement²⁻⁶. The “flip-flop” sign, an enhanced lesion shown as hypointense signals on T2-weighted images, and the “candle guttering” sign, a flame-like enhancement of the spinal parenchyma beneath the pia mater, were thought to be characteristic^{4,5}. Our patient’s MRI lacked most of the above features.

The avid contrast enhancement on MRI and CSF changes prompt the consideration of intradural-extramedullary neoplasms. Neurofibroma, lymphoma, myxopapillary ependymoma, and spinal metastasis are not very likely. Although they can cause long segmental lesions with clear margination and enhancement. Their lesions are usually hypointense on T1-weighted images and hyperintense on T2-weighted images^{7,8}. Other neoplasms, such as melanotic schwannomas and extraosseous Ewing’s sarcoma, cannot be excluded, as they can appear hyperintense on T1-weighted images and hypointense on T2-weighted images^{7,9}. Confirmatory diagnosis requires a biopsy.

Other diagnoses were less likely. Sarcoidosis can cause CSF changes similar to those in our patient. However, sarcoidosis typically presents as longitudinally extensive transverse myelitis with dorsal subpial enhancement¹⁰. Intradural-extramedullary sarcoidosis is uncommon and seldom solely presents as myelopathy. Our patient lacked multisystemic manifestations such as hepatomegaly and hilar lymphadenopathy. The ACE levels and pulmonary CT were also unremarkable.

Spinal arteriovenous fistula (sAVF) can occur in the intradural-extramedullary space, spanning multiple continuous segments. Nevertheless, CSF glucose levels are often normal in sAVF. Spinal cord edema and tortuous vessels typically appear as diffuse hyperintensities and perimedullary flow voids on T2-weighted images, with linear, heterogeneous, or diffuse patchy enhancement¹¹. The CSF profiling and absence of flow void signals in our patient argued against sAVF.

The normal brain MRI, spared optic nerves, and negative antibodies excluded primary progressive multiple sclerosis and neuromyelitis optica spectrum disorder. The normal vitamin B12 and copper levels ruled out subacute combined degeneration and copper deficiency.

What would you do next?

Section 4

To further distinguish between infection and neoplasm, whole-body PET/CT and spinal cord biopsy were indicated. The 18F-FDG-PET/CT indicated slightly increased intraspinal FDG uptake (SUV_{max}=8.6). (Figure 1D) He underwent the surgery of laminectomy and spinal cord mass resection at the C6-T1 level. The tumor was 46*14*8 mm in size, projecting in the subarachnoid space and destroying the dorsal spinal cord. Histopathology showed small round blue cells microscopically. Immunostaining was positive for NKX2.2, CD56, CD99, Synaptophysin, and Ki67 (50%) (Figure 2). Molecular analysis detected a MALAT-CYSLTR1 fusion protein and variants in oncogenic genes including *PTCH1*, *TERT*, *CREBBP*, *SPEN*, and *STK11*. The diagnosis of extraosseous Ewing's sarcoma (ES) was confirmed.

Discussion

ES is an aggressive bone and soft-tissue cancer that occurs much more frequently in children than in adults. Tumors most often arise in the long bones of the limbs and pelvis, causing nonspecific symptoms such as localized pain, swelling, and weight loss. Atypically, ES can occur in extraosseous sites, such as the liver, kidneys, uterus, orbit, bone marrow, adrenal glands, and brain, where symptoms are determined by the tumor size and location. The characteristic histopathological findings were small round blue cells in poorly differentiated tissue, which overlaps with several other malignancies including lymphoma and metastasis from nonbone tumors. Therefore, the diagnosis of ES requires a comprehensive analysis of pathology, immunochemistry, and genetics.

Histochemically, prominent membrane expression of CD99, along with frequent expression of NKX2.2, CD56, and synaptophysin, support the diagnosis of ES. An absence of CD99 essentially eliminates the diagnosis of ES. Genetically, the most common chromosomal translocation in ES is between *EWSR* and *FLT*. Other fusion proteins were also reported, suggesting the heterogeneity in ES is driven by the genetic signatures to some extent¹².

Multimodal treatment comprising surgery, chemotherapy, or radiotherapy remains to be the mainstay option. The prognosis is generally poor. Older age, metastasis, and high lactate dehydrogenase levels are unfavorable factors. Multidisciplinary treatment is beneficial to improve long-term survival.

Adult intradural-extramedullary ES is exceedingly rare. To our knowledge, this is the longest primary intraspinal ES lesion reported to date. The coexistence between extraosseous ES and neurosyphilis was also reported for the first time. Syphilis has been reported to correlate with an increased risk of various cancers. However, whether there is a causal relationship between them remains undetermined¹³.

Due to low volume of CSF sample obtained, CSF cytology was not performed. Meningeal involvement of Ewing sarcoma can yield identifiable atypical cells in CSF. Atypical cells have high nuclear cytoplasmic ratios, with irregular nuclear outlines and multiple nucleoli¹⁴. CSF cytology should not be omitted when the CSF sample volume is adequate.

Interestingly, the MALAT1-CYSLTR1 fusion protein is a novel finding. MALAT1 is a long noncoding RNA that mainly functions as a cell-cycle regulator. The overexpression of MALAT1 was correlated with metastasis and poor survival in various cancers. In ES cells, MALAT1 is transcriptionally activated through the SYK/c-MYC pathway. The silencing of MALAT1 robustly induced cell apoptosis and G1 cell-cycle arrest, implicating an oncogenic role of MALAT1 in ES pathogenesis¹⁵. More functional studies are needed to dissect the roles of MALAT1-CYSLTR1 in ES.

This patient received chemotherapy using vincristine, cyclophosphamide, and epirubicin postsurgery. His back pain was abated. However, sphincter dysfunction and paraplegia were not improved. In summary, our case detailed the diagnosis of a patient with intradural-extramedullary ES and highlighted the value of spinal cord biopsy in progressive myelopathy of unknown causes.
