Abstract

Background and Objectives: Anti-CGRP (receptor) antibodies are approved as preventive treatment for migraine. Recent concerns have been raised after a retrospective analysis of post-marketing case reports of elevated BP associated with erenumab. In this prospective follow-up study we aimed to assess the safety regarding blood pressure (BP) in a real world setting.

Methods: All people with migraine that were treated with erenumab and fremanezumab at the Leiden Headache Center between January 2019 and January 2021 were included. BP measurements were collected from baseline (T0) until 12 months follow-up, with a three-month interval (T1–T4). Mixed linear models were fitted with time as a fixed effect and the patient as a random effect.

Results: Both systolic and diastolic BP were increased at all time points T1-T4 compared to T0 (p<0.001). The maximum estimated increase in mean systolic BP was 5.2 mmHg (95% CI: 3.1-7.5). The maximum estimated increase in mean diastolic BP was 3.5 mmHg (95% CI: 2.0-4.9). In the erenumab group (n = 109), both systolic and diastolic BP were increased all time points compared to T0 (all p<0.001). For fremanezumab (n = 87), systolic but not diastolic BP was increased compared to T0 at T1 (p=0.006) and T2 (p=0.004). Four patients (3.7%) with normal BP at T0 required antihypertensive treatment after erenumab was started.

Discussion: The mean systolic and diastolic BP increased after anti-CGRP (receptor) antibodies were started. The majority of patients remained within the normal blood pressure limits, but some patients required antihypertensive treatment. Physicians should be aware that people with migraine may be at risk to develop hypertension when treated with anti-CGRP (receptor) antibodies and this should be added to (inter)national treatment guidelines.

Classification of Evidence: This study provides Class III evidence that anti-CGRP (receptor) antibodies increase blood pressure when used to treat patients with migraine.
Introduction

Migraine is a primary headache disorder, characterized by recurrent moderate to severe headaches, accompanied by photo- and phonophobia and/or severe nausea and/or vomiting. The pathophysiology is not completely uncovered, however, CGRP has been identified to play a major role. Recently new preventive migraine treatments targeting calcitonin gene-related peptide (CGRP) have become available; three monoclonal antibodies targeting the ligand CGRP (eptinezumab, fremanezumab and galcanezumab) and one targeting the CGRP receptor (erenumab).

CGRP is known to be a very potent vasodilator. Besides its role in migraine, CGRP is involved in blood pressure (BP) regulation. Therefore, the use of these monoclonal antibodies may potentially lead to hypertension. No increased risk of hypertension or other cardiovascular disease has been reported in any of the randomized placebo-controlled clinical trials. Nevertheless, recent concerns have been raised after a retrospective analysis of post-marketing case reports of elevated BP associated with erenumab. Sixty-one cases of elevated BP related to treatment with erenumab were reported to the FDA. In contrast, no such concern yet has been reported regarding a CGRP antibody. As migraine itself is associated with an increased risk for cardio- and cerebrovascular events, it is important that anti-CGRP treatment does not increase this risk even more.

In this prospective follow up study we assessed whether treatment with the preventive drugs erenumab and fremanezumab changes systolic and diastolic BP in people with migraine during one year follow-up.

Methods

Participants

All people with migraine receiving treatment with erenumab or fremanezumab between January 2019 till January 2021 at the Leiden Headache Center, a national academic referral center in the Netherlands, were deemed eligible for participation. Patients were included if blood pressure (BP) measurements were present at baseline and patients had a follow up of at least 6 months. All patients were diagnosed with migraine by a neurology resident in consultation with a headache specialist or by a neurologist with headache expertise, according to the ICHD-3 criteria. None of the patients had medication overuse headache at treatment initiation. With restricted availability of erenumab and fremanezumab we were able to include patients with ≥8 migraine days, who failed on ≥4 migraine preventives (meaning
being ineffective, discontinued because of side effects or being contraindicated), including at least a betablocker, candesartan, valproate and topiramate. Erenumab could be prescribed to patients aged 18-65 years and fremanezumab to patients aged 18-70 years.

Treatment
Patients treated with erenumab started with 70 mg, administered subcutaneously once every four weeks and optionally increased this to 140 mg after at least 3 months based on a shared decision between patients’ and physicians’ impression of effectiveness. Fremanezumab was prescribed as 225 mg subcutaneous injection every four weeks. Patients were not treated with additional preventive treatment.

Blood pressure
BP measurements (mmHg) were collected from the electronic patient records. Patients had a consultation at the Leiden Headache Center at start (T0) and approximately every three months until treatment was discontinued. As part of regular clinical care, BP was measured in sitting position during these consultations with an automatic BP device by the treating physician or a nurse. Data were collected from baseline (before starting treatment, T0) and every follow-up visit hereafter with a maximum follow-up of 12 months (T1 to T4). Patients were excluded from analyses if baseline BP was measured while patients were still tapering off current migraine preventive treatment that may affect BP, such as betablockers or candesartan.

Patients not able to come to a physical visit (e.g. during COVID-lockdown) were sometimes asked to measure their BP at home or at the general practitioner. However, only BP measurements obtained at the Leiden Headache Center were included in our analyses. Hypertension was not an exclusion criterion for starting treatment with erenumab or fremanezumab. Patients with elevated BP (according to international blood pressure guidelines\textsuperscript{9,10}) at any time during treatment were referred to their general practitioner for additional measurements (e.g. 24-hour measurements) and received treatment if deemed necessary. If patients started treatment with antihypertensive drugs, the follow-up BP values hereafter were excluded from the analyses. If patients were already treated for hypertension before starting erenumab or fremanezumab, their measurements would only be included if there was no dose or drug change in their antihypertensive drugs.

Control group

Copyright © 2022 The Author(s). Published by Wolters Kluwer Health, Inc. on behalf of the American Academy of Neurology.
As a control group we included people with migraine of the Leiden Headache Center with similar distribution in gender, age and migraine diagnosis. These patients did not use any migraine prophylactic treatment or other medication that would possibly influence their blood pressure. Blood pressure was measured in these patients as part of regular care. We collected blood pressure measurements from two different timepoints (time range 1-3 months).

**Statistics**

Sample size was based on the available data. Baseline characteristics, including sex, age, headache diagnosis, baseline headache and migraine days were summarized using means, standard deviations, frequencies and proportions.

For both systolic and diastolic BP, a linear mixed model was fitted with time and treatment (erenumab or fremanezumab) as fixed effects and the patient as a random effect. For the primary outcome, these analyses were performed for the total study population. As a secondary analysis, the mixed models were repeated for erenumab and fremanezumab separately. The control group was analyzed in the same manner.

The number of patients with hypertension or a relevant increase in blood pressure during the course of treatment were assessed in three ways: 1) Patients who started treatment with antihypertensive drugs during treatment with erenumab or fremanezumab 2) Patients with a systolic BP ≥140 mmHg and/or diastolic BP ≥90 mmHg at any time during follow-up 3) Patients with an increase in systolic blood pressure ≥20 mmHg and/or an increase in diastolic BP ≥10 mmHg at any time during follow-up. The patients who started antihypertensive treatment for hypertension were described in detail, including but not limited to age, gender, BMI, baseline BP and maximum BP measured.

Missing values were not imputed. In all analyses two-sided p-values <0.05 were considered to be significant. All statistical analyses were performed using IBM SPSS Statistics for Windows, version 25 (IBM Corp., Armonk, N.Y., USA).

**Sensitivity analysis**

For a post-hoc sensitivity analysis, missing blood pressure measurements were handled using multiple imputation. Ten imputed datasets on systolic and diastolic blood pressure were generated using automatic imputation. The linear mixed model as described above was repeated using the imputed dataset.
Results
A total of 211 patients started treatment with the anti-CGRP (receptor) antibodies erenumab or fremanezumab. In seven patients baseline BP was missing and in eight patients baseline BP was measured while they were still tapering off a betablocker or candesartan. Two patients were already treated for hypertension, but their medication did not change during the course of this study, and thus these patients were included in the analyses. We included 109 patients who started treatment with erenumab and 87 patients who started treatment with fremanezumab.

Among the patients treated with erenumab, 93 (85%) were female, the average age was 42 years and 55 (51%) patients had chronic migraine. Among the patients treated with fremanezumab, 74 (85%) were women, the average age was 45 years and 48 (55%) patients had chronic migraine. Baseline characteristics for both study groups are presented in Table 1.

The number of patients of whom BP measurements were available at every time point are shown in the flowchart of figure 1. Data could be missing because patients discontinued treatment, the BP was not measured at the Leiden Headache Center, because patients’ follow-up time was less than 12 months, or if BP treatment was initiated.

Blood pressure in total study population
We observed an increase in systolic BP at all time points compared to baseline (Figure 2). At T1, systolic BP increased with 5.0 mmHg (95% CI: 3.1 to 6.9, p<0.001). At T2, the estimated effect was 4.9 mmHg (95% CI: 2.9 to 7.0, p<0.001). At T3, the estimated effect compared to baseline was 4.7 mmHg (95% CI: 2.5 to 6.9, p<0.001). At T4, the systolic BP increased by 5.2 mmHg (95% CI: 3.1 to 7.5, p<0.001). A larger estimated effect from erenumab than from...
fremanezumab was found for the increase in systolic blood pressure ($\beta \pm SE = 4.3 \pm 1.9$, $p = 0.03$).

The diastolic BP increased as well at all time points compared to baseline (Figure 2). At T1, diastolic BP increased by 3.3 mmHg (95% CI: 2.1 to 4.5, $p<0.001$). At T2, the estimated effect was 3.2 mmHg (95% CI: 1.8 to 4.5, $p<0.001$). At T3, the estimated effect compared to baseline was 2.5 mmHg (95% CI: 1.0 to 3.9, $p<0.001$). At T4, the diastolic BP increased by 3.5 mmHg (95% CI: 2.0 to 4.9, $p<0.001$). A larger estimated effect from erenumab than from fremanezumab was found for the increase in diastolic blood pressure ($\beta \pm SE = 2.4 \pm 1.1$, $p = 0.03$).

Blood pressure in patients treated with erenumab
In the erenumab subgroup, we found an increase in systolic BP at all time points compared to baseline (Figure 3). At T1, the systolic BP increased by 5.8 mmHg (95% CI: 3.3 to 8.3, $p<0.001$). At T2, the estimated effect was 5.0 mmHg (95% CI: 2.3 to 7.7, $p<0.001$). At T3, the estimated effect was 7.6 mmHg (95% CI: 4.6 to 10.5, $p<0.001$). At T4, the systolic BP increased by 9.1 mmHg (95% CI: 6.2 to 12.0, $p<0.001$).

The diastolic BP increased as well at all time points compared to baseline (Figure 3). At T1, diastolic BP increased by 4.9 mmHg (95% CI: 3.1 to 6.8, $p<0.001$). At T2, the estimated effect was 5.8 mmHg (95% CI: 3.9 to 7.8, $p<0.001$). At T4, the diastolic BP increased by 6.3 mmHg (95% CI: 4.4 to 8.3, $p<0.001$).

Blood pressure in patients treated with fremanezumab
For fremanezumab, we found an increase in systolic BP at T1 and T2, but not at T3 and T4 (Figure 3). At T1, systolic BP increased by 3.8 mmHg (95% CI: 1.1 to 6.6, $p = 0.006$). At T2, it increased by 4.6 mmHg (95% CI: 1.5 to 7.7, $p = 0.004$). At T3, the estimated effect compared to baseline was 1.6 mmHg (95% CI: -1.6 to 4.8, $p = 0.31$). At T4, the estimated effect was 0.9 mmHg (95% CI: -2.4 to 4.2, $p = 0.59$).

The diastolic BP in patients treated with fremanezumab did not increase (Figure 3). At T1, the mean difference was 0.8 mmHg (95% CI: -0.8 to 2.5, $p = 0.33$). At T2, the estimated effect was 0.8 mmHg (95% CI: -1.0 to 2.7, $p = 0.39$). At T3, the estimated effect compared to baseline was -1.4 mmHg (95% CI: -3.3 to 0.5, $p = 0.16$). At T4, the estimated effect was by -0.02 mmHg (95% CI: -2.0 to 2.0, $p = 0.99$).
Patients starting antihypertensive drugs

In total, nine patients started antihypertensive drugs during the course of treatment with erenumab (5/9) or fremanezumab (4/9). Five of these patients were referred to their general practitioner after the baseline BP measurement, but CGRP-blocking treatment was started before antihypertensive treatment was started. Four patients (3.7%) with normal BP at T0 required antihypertensive treatment after erenumab was started. Patient characteristics are provided in Table 2.

Patients with elevated blood pressure

Of all patients, 53 patients had a systolic BP ≥ 140 mmHg and/or a diastolic BP ≥ 90 mmHg at any time during course of treatment with erenumab (33/109) or fremanezumab (20/87), while at baseline BP was <140/90 mmHg. In total, 76 patients had a systolic BP rise of ≥ 20 mmHg and/or a diastolic BP rise ≥ 10 mmHg at any time during the course of treatment with erenumab (52/109, 47.7%) or fremanezumab (24/87, 27.6%). In about half of these patients (total 41 patients, erenumab 28 patients, fremanezumab 13 patients) this BP rise did not lead to a systolic BP ≥ 140 mmHg and/or a diastolic BP ≥ 90 mmHg.

Control group

A total of 109 people with migraine were included in the control group. Average systolic BP of the first measurement was 121.3 ± 14.9 mmHg and the average diastolic BP was 77.0 ± 9.9 mmHg. The average follow-up systolic BP was 120.9 ± 14.8 mmHg and the average follow-up diastolic BP was 77.7 ± 8.7 mmHg. There was no change over time in systolic (p = 0.70) or diastolic (p = 0.39) blood pressure.

Sensitivity analysis

In the analysis with the imputed dataset, the systolic BP increased at all time points compared to baseline. At T1, systolic BP increased with 5.3 mmHg (95% CI: 2.7 to 7.9, p<0.001). At T2, the estimated effect was 4.3 mmHg (95% CI: 1.1 to 7.5, p=0.009). At T3, the estimated effect compared to baseline was 4.3 mmHg (95% CI: 1.2 to 7.5, p=0.004). At T4, the systolic BP increased by 3.7 mmHg (95% CI: 0.8 to 6.5, p=0.01). A larger estimated effect from erenumab than from fremanezumab was found for the increase in systolic blood pressure (β ± SE = 2.2 ± 0.8, p = 0.004).
Likewise, the diastolic BP increased at all time points compared to baseline. At T1, diastolic BP increased by 3.2 mmHg (95% CI: 1.6 to 4.7, p<0.001). At T2, the estimated effect was 2.7 mmHg (95% CI: 0.7 to 4.7, p=0.01). At T3, the estimated effect compared to baseline was 2.1 mmHg (95% CI: 0.4 to 3.7, p=0.01). At T4, the diastolic BP increased by 2.5 mmHg (95% CI: 0.6 to 4.4, p=0.01). A larger estimated effect from erenumab than from fremanezumab was found for the increase in diastolic blood pressure (β ± SE = 1.1 ± 0.5, p = 0.02).

Classification of evidence

This study provides Class III evidence that anti-CGRP (receptor) antibodies increase blood pressure when used to treat patients with migraine.

Discussion

We collected blood pressure (BP) measurements in a prospective one year follow-up study of patients with migraine treated with erenumab and fremanezumab at the Leiden Headache Center. Already at the first follow-up visit, after three months of treatment, an increase in both mean systolic and mean diastolic BP was observed. Furthermore, the increase in mean systolic and mean diastolic blood pressure was a long lasting effect, lasting the entire follow-up period of 12 months. For some patients (3.7% of the patients treated with erenumab), this required the start of antihypertensive treatment. Of all patients, 75 (38%) had a relevant increase in BP (i.e. ≥20 mmHg systolic and/or ≥10 mmHg diastolic) at any time during follow-up, while half of these patients remained within the normal blood pressure limits.

In line with the clinical trials of erenumab and fremanezumab,11,12 we did not find a major risk of developing hypertension. While, fortunately, the majority of patients did not require treatment for hypertension, we did observe a modest effect on the mean BP. It is important to realize that BP and cardiovascular events have a continuous relation.13 The cut-off values of hypertension are the levels of BP at which it was demonstrated that the benefits of treatment outweigh the risks of antihypertensive treatment.9 Previous studies indicated that CGRP does not seem to have a role in the physiological regulation of normal BP3, but that it provides a key compensatory mechanism against hypertension.14 Thus, while a potential risk of hypertension may arise when patients are treated with CGRP blocking medication, it may be that blocking CGRP is only potentially problematic for patients already at risk of developing hypertension. After the first observed increase after three months of treatment,
the mean systolic and diastolic BP remained stable. This is consistent with the fact that in the majority of cases reported to the FDA the hypertension was detected in the first week(s) after the first erenumab injection. This suggests that whether a patient develops hypertension, will be apparent soon after initiating treatment. At the same time, it seems that the rise in BP is a long lasting effect of treatment and no adaptation process takes place within at least 12 months. This long lasting effect, together with the results of our control group, also make it less likely that the increase we found is due to natural fluctuation.

Our data suggest that there might be a different effect for erenumab than for fremanezumab. Our results seem to demonstrate a larger and more consistent effect on the BP in patients treated with erenumab than in patients treated with fremanezumab. We cannot for certain conclude whether there are indeed differences between these two drugs or what the reason for these differences would be. One reason could be that erenumab might have a larger inhibiting effect on the CGRP-pathway than fremanezumab, although this seems unlikely given the similar clinical efficacy of both drugs. An alternative explanation arises from the fact that erenumab (an antibody against the CGRP receptor) and fremanezumab (an antibody against the peptide CGRP) affect the CGRP-pathway in different ways, which could hypothetically lead to clinical differences due to differences in receptor internalization and/or action of other ligands on receptors from the CGRP family. A third possible explanation would be that there might have been a lack of statistical power in the analyses for the fremanezumab subgroup. In addition, we did not randomly assign patients to treatment with erenumab or fremanezumab. Although the baseline characteristics seem similar, it might be that there is a difference between the two patient populations. Lastly, although for erenumab previous data suggested an effect on BP, for fremanezumab data are still limited. In a previous study a single dose of fremanezumab did not cause any change in systolic or diastolic BP. However, the sample size in that study was extremely small, only 23 healthy women receiving different dosages of fremanezumab. A recent abstract presenting blood pressure data of the clinical trials with fremanezumab, described no changes in either systolic or diastolic BP. Unfortunately, no information was provided on the use and changes in dosage of blood pressure medication. Further research is necessary to confirm the potential differences between erenumab and fremanezumab and to examine the possible explanations for such differences.

It may be that increasing the dosage from 70 to 140 mg would increase the blood pressure further in patients. However, while the majority of patients did increase the dosage to 140 mg at some point during follow up, we did not see a significant increase in month 6, 9, or 12 compared to month 3. However, for these analyses our study might be underpowered. An
additional limitation of this study is the risk of a white coat effect when measuring BP in the
doctor’s office.\textsuperscript{19} This could have led to an overestimation of the number of patients with a
BP $\geq 140/90$ mmHg. However, by including exclusively values measured at the Leiden
Headache Center we intended to reduce the variability and to remain the reliability of the
measurements. All BP measurements were performed by a health care professional with the
same type of BP device. If there were a white coat effect, it would account also for the
baseline measurement, and therefore cannot be an explanation for the increase in BP.
Additionally, antihypertensive medication was not prescribed based on the BP measured at
the headache center. The general practitioner made this decision based on additional
measurements and BP guidelines.\textsuperscript{10,20} A third potential limitation of this study comes from
excluding BP measurements after patients started treatment for hypertension. However, this
probably caused an underestimation of the rise in blood pressure, and thus is unlikely to
affect our conclusions. Lastly, we realize that the missing data could have influenced the
results. Therefore we performed a sensitivity analysis, after multiple imputation, which did
not demonstrate different results.

In our patient population only 3.7\% of patients treated with erenumab had newly onset
hypertension requiring treatment, which is not sufficient to identify patient-specific risk
factors. Currently known risk factors for hypertension in the general population include
modifiable risk factors such as higher BMI and smoking, and unmodifiable risk factors such
as higher age, family history of hypertension and co-existing diseases such as diabetes and
kidney disease. It is uncertain whether the same risk factors can be applied to this specific
patient group. Interestingly, the age range of the post marketing cases reported at the FDA
was 24-88, suggesting that not only older patients are at risk.\textsuperscript{5} In addition, a seemingly
obvious risk factor would be tapering off preventive migraine treatment with antihypertensive
properties, such as candesartan and beta-blockers, before starting treatment with anti-
CGRP (receptor) antibodies. However, as mentioned above, this was an exclusion criterion
on our study, and therefore this was not the case in any of the patients in our study who
developed hypertension requiring treatment. Furthermore, NSAIDs are known to be able to
increase blood pressure. However, as acute medication use diminished during follow-up\textsuperscript{21},
this is not likely a cause for the increase in blood pressure. More real-life data might help to
identify patient-specific risk factors for developing hypertension regarding treatment with
CGRP (receptor)-targeting antibodies, which will be important to include in clinical treatment
guidelines. We believe it is of utmost importance to monitor BP in real world settings in
patients treated with CGRP-targeting drugs. Hypertension in people with migraine is
suggested to be associated with conversion from episodic to chronic migraine.\textsuperscript{22} Moreover,
people with migraine, especially women and those people with migraine with aura, already
have a vascular vulnerability\textsuperscript{23} with an increased risk of white matter lesions\textsuperscript{24,25}, stroke\textsuperscript{7,8}
and coronary heart disease\textsuperscript{6} with underlying shared genetic mechanisms.\textsuperscript{26,27} Hypertension is known to be the most important modifiable risk factor for cardiovascular disease.\textsuperscript{28} Therefore, timely detection of elevated BP is essential for adequate intervention.

Conclusion

The mean systolic and diastolic BP slightly increased after starting treatment with erenumab or fremanezumab. Fortunately, the majority of patients did not require treatment with antihypertensive drugs. As CGRP appears to provide a protective mechanism in hypertension, blocking CGRP could be specifically problematic for patients already at risk of developing hypertension. As migraine itself is associated with an increased risk for cardio- and cerebrovascular events, it is important to monitor the BP after starting treatment with CGRP targeting treatment to prevent increasing this risk. Physicians should be aware of the possibility that people with migraine develop hypertension when treating them with anti-CGRP (receptor) antibodies. Caution for raised BP regarding anti-CGRP (receptor) antibodies should be added to clinical treatment guidelines for migraine.

Gender: F = female, M = male. MA = migraine with aura, MO = migraine without aura. T0 = baseline. Mab = monoclonal antibody. RR in mmHg.
Figure 1 Flowchart

Number of patients included in the analysis at every timepoint of the study and reasons for missing data. Left side: total number of patients available at the different time points. Right side: number of missing data divided in not measured, discontinued treatment, excluded due to starting antihypertensive treatment or shorter follow-up time. Main reason for not measuring the blood pressure at follow up was that these patients consulted our clinic through telemedicine (video consultation) due to lock-down measurements because of COVID-19.
Figure 2  Blood pressure development during 12 month follow-up after starting erenumab or fremanezumab. Data presented in mean ± 95% CI. Asterisks present significant change compared to baseline: * < p < 0.05, ** p < 0.01, *** p < 0.001.

Figure 3  Blood pressure development during 12 month follow-up separately for erenumab and fremanezumab. Data presented in mean ± 95% CI. Asterisks present significant change compared to baseline: * < p < 0.05, ** p < 0.01, *** p < 0.001.
Blood Pressure in Migraine Patients Treated With Monoclonal Anti-CGRP (receptor) Antibodies: A Prospective Follow-up Study
